Exercise 1 (4 + 3 + 4 + 5 + 6 = 22 points)

The following data structure represents polymorphic lists that can contain values of *two* types in arbitrary order:

data DuoList a b = C a (DuoList a b) | D b (DuoList a b) | E

Consider the following list **zs** of integers and characters:

The representation of zs as an object of type DuoList Int Char in Haskell would be:

C 4 (D 'a' (D 'b' (C 6 E)))

Implement the following functions in Haskell.

(a) The function foldDuo of type

$$(a \rightarrow c \rightarrow c) \rightarrow (b \rightarrow c \rightarrow c) \rightarrow c \rightarrow DuoList a b \rightarrow c$$

works as follows: foldDuo f g h xs replaces all occurrences of the constructor C in the list xs by f, it replaces all occurrences of the constructor D in xs by g, and it replaces all occurrences of the constructor E in xs by h. So for the list zs above,

foldDuo (*) (
$$x y \rightarrow y$$
) 3 zs

should compute

which in the end results in 72. Here, C is replaced by (*), D is replaced by ($x y \rightarrow y$), and E is replaced by 3.

foldDuo f g h (C x xs) = f x (foldDuo f g h xs)
foldDuo f g h (D x xs) = g x (foldDuo f g h xs)
foldDuo f g h E = h

First name	Last name	Matriculation number

(b) Use the foldDuo function from (a) to implement the cd function which has the type DuoList Int a -> Int and returns the sum of the *entries* under the data constructor C and of the *number of elements* built with the data constructor D.

In our example above, the call cd zs should have the result 12. The reason is that zs contains the entries 4 and 6 under the constructor C and it contains two elements 'a' and 'b' built with the data constructor D.

cd = foldDuo (+) ($x y \rightarrow y + 1$) 0

 $\mathbf{2}$

(c) Consider the following data type declaration for natural numbers:

```
data Nats = Zero | Succ Nats
```

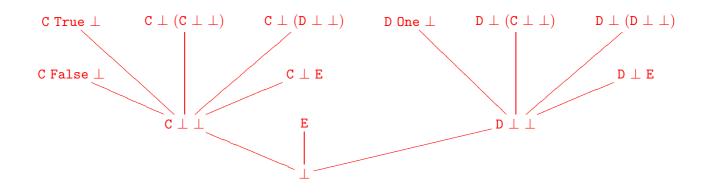

A graphical representation of the first four levels of the domain for Nats could look like this:

We define the following data type Single, which has only one data constructor One:

data Single = One

Sketch a graphical representation of the first three levels of the domain for the data type DuoList Bool Single.

First name	Last name	Matriculation number

(d) Write a Haskell function printLength that first reads a line from the user, then prints this string on the console and in the end also prints the length of this string on the console. Also give the type declaration for your function.

You may use the do-notation, but you are not obliged to use it. Some of the following pre-defined functions can be helpful:

- getLine :: IO String reads a line from the user
- length :: String -> Int has the length of a string as its result
- show :: Int -> String converts a number to a string
- putStr :: String -> IO () writes a string to the console

An example run should look as given below. Here the string "foo" was read from the user.

```
Main> printLength
foo
foo3
```

First name	Last name	Matriculation number

(e) The digit sum of a natural number is the sum of all digits of its decimal representation. For example, the digit sum of the number 6042 is 6 + 0 + 4 + 2 = 12. Write a Haskell function digitSum :: Int -> Int that takes a natural number and returns its digit sum. Your function may behave arbitrarily on negative numbers. It can be helpful to use the pre-defined functions div, mod :: Int -> Int -> Int to compute result and remainder of division, respectively. For example, div 7 3 is 2 and mod 7 3 is 1.

```
digitSum :: Int -> Int
digitSum 0 = 0
digitSum (n+1) = mod (n+1) 10 + digitSum (div (n+1) 10)
```

Now implement a function digitSumList :: Int -> Int -> [Int] where digitSumList n b returns a list of all those numbers x where $0 \le x \le b$ and where the digit sum of x is n. Perform your implementation only with the help of a list comprehension, i.e., you should use exactly one declaration of the following form:

digitSumList ... = [... | ...]

Of course, here you can (and should) make use of the function digitSum to compute the digit sum of a number.

```
digitSumList :: Int -> Int -> [Int]
digitSumList n b = [ x | x <- [0..b], digitSum x == n ]</pre>
```

Exercise 2 (4 + 5 = 9 points)

Consider the following Haskell declarations for the square function:

square :: Int \rightarrow Int square 0 = 0 square (x+1) = 1 + 2*x + square x

(a) Please give the Haskell declarations for the higher-order function f_square corresponding to square, i.e., the higher-order function f_square such that the least fixpoint of f_square is square. In addition to the function declaration(s), please also give the type declaration of f_square. Since you may use full Haskell for f_square, you do not need to translate square into simple Haskell.

f_square :: (Int -> Int) -> (Int -> Int) f_square square 0 = 0 f_square square (x+1) = 1 + 2*x + square x

(b) We add the Haskell declaration bot = bot. For each n ∈ N please determine which function is computed by f_squareⁿ bot. Here "f_squareⁿ bot" represents the n-fold application of f_square to bot, i.e., it is short for f_square (f_square ... (f_square bot)...).

n times

6

Let $f_n : \mathbb{Z}_{\perp} \to \mathbb{Z}_{\perp}$ be the function that is computed by f_square^n bot. Give f_n in closed form, i.e., using a non-recursive definition.

 $(\texttt{f_square}^n(\bot))(x) = \begin{cases} x^2, & \text{if } 0 \le x < n \\ \bot, & \text{otherwise} \end{cases}$

Exercise 3 (6 points)

Let D_1, D_2 be domains, let \sqsubseteq_{D_2} be a complete partial order on D_2 . As we know from the lecture, then also $\sqsubseteq_{D_1 \to D_2}$ is a complete partial order on the set of all functions from D_1 to D_2 .

Prove that $\sqsubseteq_{D_1 \to D_2}$ is also a complete partial order on the set of all *constant* functions from D_1 to D_2 . A function $f: D_1 \to D_2$ is called *constant* iff f(x) = f(y) holds for all $x, y \in D_1$.

Hint: The following lemma may be helpful:

If S is a chain of functions from D_1 to D_2 , then $\sqcup S$ is the function with:

$$(\sqcup S)(x) = \sqcup \{ f(x) \mid f \in S \}$$

We need to show two statements:

a) The set of all constant functions from D_1 to D_2 has a smallest element \perp .

Obviously, the constant function f with $f(x) = \bot$ for all $x \in D_1$ satisfies this requirement.

b) For every chain S on the set of all constant functions from D_1 to D_2 there is a least upper bound $\sqcup S$ which is an element of the set of all constant functions from D_1 to D_2 .

Let S be a chain of constant functions from D_1 to D_2 . By the above lemma, we have $(\sqcup S)(x) = \sqcup \{f(x) \mid f \in S\}$. It remains to show that the function $\sqcup S : D_1 \to D_2$ actually is a constant function. For all $x, y \in D_1$, we have:

$$(\sqcup S)(x)$$

= $\sqcup \{f(x) \mid f \in S\}$
= $\sqcup \{f(y) \mid f \in S\}$ since the elements of S are constant functions
= $(\sqcup S)(y)$

Therefore, also $(\sqcup S)(x)$ is a constant function.

Exercise 4 (4 + 5 = 9 points)

Consider the following data structure for polymorphic lists:

data List a = Nil | Cons a (List a)

(a) Please translate the following Haskell-expression into an equivalent lambda term (e.g., using $\mathcal{L}am$). Recall that pre-defined functions like even are translated into constants of the lambda calculus.

It suffices to give the result of the transformation.

```
let f = x \rightarrow if (even x) then Nil else Cons x (f x) in f
```

(fix $(\lambda f \ x. \ if (even \ x) \ Nil (Cons \ x \ (f \ x))))$

First name	Last name	Matriculation number

(b) Let δ be the set of rules for evaluating the lambda terms resulting from Haskell, i.e., δ contains at least the following rules:

$$\begin{array}{rcl} \texttt{fix} & \to & \lambda f. \; f \; (\texttt{fix} \; f) \\ \texttt{plus 23} & \to & \texttt{5} \end{array}$$

Now let the lambda term t be defined as follows:

 $t = (\text{fix} (\lambda g \ x. \text{ Cons (plus } x \ 3) \text{ Nil})) 2$

Please reduce the lambda term t by WHNO-reduction with the $\rightarrow_{\beta\delta}$ -relation. You have to give **all** intermediate steps until you reach **weak head normal form** (and no further steps).

 $\begin{array}{l} (\texttt{fix}\;(\lambda g\;x.\;\texttt{Cons}\;(\texttt{plus}\;x\;3)\;\texttt{Nil}))\;2\\ \rightarrow_{\delta} & ((\lambda f.\;f\;(\texttt{fix}\;f))\;(\lambda g\;x.\;\texttt{Cons}\;(\texttt{plus}\;x\;3)\;\texttt{Nil}))\;2\\ \rightarrow_{\beta} & ((\lambda g\;x.\;\texttt{Cons}\;(\texttt{plus}\;x\;3)\;\texttt{Nil})\;(\texttt{fix}\;(\lambda g\;x.\;\texttt{Cons}\;(\texttt{plus}\;x\;3)\;\texttt{Nil})))\;2\\ \rightarrow_{\beta} & ((\lambda x.\;\texttt{Cons}\;(\texttt{plus}\;x\;3)\;\texttt{Nil})\;2\\ \rightarrow_{\beta} & (\texttt{cons}\;(\texttt{plus}\;x\;3)\;\texttt{Nil})\;2\\ \rightarrow_{\beta} & \texttt{Cons}\;(\texttt{plus}\;2\;3)\;\texttt{Nil}\end{array}$

Exercise 5 (10 points)

Use the type inference algorithm \mathcal{W} to determine the most general type of the following lambda term under the initial type assumption A_0 . Show the results of all sub-computations and unifications, too. If the term is not well typed, show how and why the \mathcal{W} -algorithm detects this.

```
\lambda f. (Succ (f x))
```

The initial type assumption A_0 contains at least the following:

$$\begin{array}{lll} A_0(\texttt{Succ}) &=& (\texttt{Nats} \to \texttt{Nats}) \\ A_0(f) &=& \forall a. \ a \\ A_0(x) &=& \forall a. \ a \end{array}$$

$$\begin{split} \mathcal{W}(A_0, \ \lambda f. \ (\texttt{Succ} \ (f \ x)) \) \\ \mathcal{W}(A_0 + \{f :: b_1\}, \ (\texttt{Succ} \ (f \ x)) \) \\ \mathcal{W}(A_0 + \{f :: b_1\}, \ \texttt{Succ}) \\ &= (id, \ (\texttt{Nats} \to \texttt{Nats}) \) \\ \mathcal{W}(A_0 + \{f :: b_1\}, \ (f \ x) \) \\ \mathcal{W}(A_0 + \{f :: b_1\}, \ f) \\ &= (id, \ b_1) \\ \mathcal{W}(A_0 + \{f :: b_1\}, \ x) \\ &= (id, \ b_2) \\ mgu(b_1, \ (b_2 \to b_3) \) = [b_1/(b_2 \to b_3)] \\ &= ([b_1/(b_2 \to \texttt{Nats}), \ (b_3 \to b_4) \) = [b_3/\texttt{Nats}, b_4/\texttt{Nats}] \\ &= ([b_1/(b_2 \to \texttt{Nats}), b_3/\texttt{Nats}, b_4/\texttt{Nats}], \ \texttt{Nats}) \to \texttt{Nats}) \) \end{split}$$

Resulting type: $((b_2 \rightarrow \texttt{Nats}) \rightarrow \texttt{Nats})$
